Overview#

Though the OS is written in C, the memory manager implementation supports an object-oriented concept: [polymorphism](#). There is a global variable called *memmgr* that defines an API to the memory manager. The type of the object is [struct memmgr_entry](#), which defines a few data fields and a whole bunch of functions.

Throughout the code we make a lot of references to the *memmgr* variable. For example, when we need to change address spaces we call *memmgr.ospace()*.

But what's behind the *memmgr* variable? It could be any of a couple of different memory manager implementations. In practice, it's always the virtual memory manager (implemented in *services/system/memmgr/vmm*.**) but it's possible that it could be the physical memory manager (*services/system/memmgr/pmm*.**) or the runtime-executive memory manager (*services/system/ker/emm*.** and *services/system/ker/smm*.**).

When the system initializes, one of those memory managers is assigned to the *memmgr* variable (have a look at the *init_memmgr()* function at the end of [memmgr_init.c](#)). As I said, in practice it's always the virtual memory manager but the others are possible. But when you're looking at the kernel code and you see something like a call to *memmgr.foo()*, you can assume that *memmgr.foo()* is implemented with *vmm_foo()*.

For a more detailed look at the design of the memory manager, refer to [Virtual memory manager data structures](#) and [Virtual memory manager algorithms](#).
